Abstract

The Alcriss project aims to perform a long term survey of the radiation environment on board the International Space Station. Measurements are being performed with active and passive devices in different locations and orientations of the Russian segment of the station. The goal is to perform a detailed evaluation of the differences in particle fluence and nuclear composition due to different shielding material and attitude of the station. The Sileye-3/Alteino detector is used to identify nuclei up to Iron in the energy range above $\simeq 60$ MeV/n. Several passive dosimeters (TLDs, CR39) are also placed in the same location of Sileye-3 detector. Polyethylene shielding is periodically interposed in front of the detectors to evaluate the effectiveness of shielding on the nuclear component of the cosmic radiation. The project was submitted to ESA in reply to the AO in the Life and Physical Science of 2004 and data taking began in December 2005. Dosimeters and data cards are rotated every six months: up to now three launches of dosimeters and data cards have been performed and have been returned with the end of expedition 12 and 13.

Key words: Cosmic Rays, Nuclear Abundances, International Space Station, Radiation Shielding
PACS: 96.40-z, 95.55-n

1 Introduction

The International Space Station is a unique testbed for long term human permanence in space and a proving ground for future missions to the Moon and Mars. With these missions it is expected that human presence in space will increase both in the number of space travellers and the duration of the missions(1; 2; 3). Therefore a detailed knowledge of the radiation field in space, its effects on human physiology and the associated risk have been and will be needed in mission planning. In addition to a detailed understanding of the biological effects on the human body(4), this task requires precise measurements of the particles in the cosmic ray environment, their temporal variations due to solar modulation or Solar Particle Events and their orbital dependence (due to geomagnetic cutoff and trapped particles encountered in the South Atlantic Anomaly) as well as to how these particles interact with the hull of the station. Nuclear abundances and differential spectra of cosmic ray nuclei have been studied over a wide energy range and in different points of the Heliosphere by a number of spacecrafts (e.g. ACE, Sampex, Ulysses). This has greatly advanced the knowledge of the cosmic ray composition and the phys-

ical phenomena involved such as solar modulation, solar energetic particles, trapping of particles in the radiation belts and so on. Cosmic rays, consisting of 99% H and He ions and 1% heavier nuclei (which - however - represent the dominant component of the equivalent dose(5)) interact with the spacecraft material, producing secondary particles that result in modified nuclear abundances and energy spectrum(6). For these reasons the radiation environment on board the ISS is being monitored by a number of different detectors employing different techniques(7; 8; 9; 10; 11; 12; 13; 14). Due to the large inhomogeneity in the hull of the station, it is still an open question to assess *a priori* the cosmic ray flux and the corresponding dose rate in the different points of the station(16; 15; 17; 18). Furthermore, to these uncertainties one must add the effects of a densely ionizing field on the human body, such as the accurate estimation of the damage to cells and the associated risk induced by heavily charged radiation on astronauts(19; 20; 21). Radiation evaluation and protection in space is therefore an interdisciplinary field, involving scientists from many areas, such as cosmic ray physics, radiobiology, dosimetry and computer science.

2 The Altriss project

The Altriss (Alteino Long Term Monitoring of Cosmic Rays on the International Space Station) project aims to perform a long term survey of the radiation and cosmic ray environment on board the ISS. It was submitted to ESA in response to the AO in Life and Physical Science of 2004 with observations beginning at the end of 2005 (increment 12) and expected to continue for three years. This experiment follows previous ones on Mir where relative nuclear abundances and Light Flash perception(22; 23; 24) measurements have been performed with similar silicon detector based devices (Sileye-1 and Sileye-2). Previous measurements on ISS with Sileye-3/Alteino have been performed in 2002 and 2005 in the framework of the first and second Italian-Soyuz Missions. In those missions measurements were limited to the taxi flight duration (< 10 days each) and to the Pirs module. The main goals of this project are:

- *Monitoring of long and short term solar modulation of cosmic rays.* The active nature of the device allows to identify particles of galactic, trapped and solar origin according to their position and temporal profile. Observations are currently being carried at solar minimum, going toward solar maximum.
- *Observations of Solar Particle Events.* We expect in three years(25) about 10 events with an energy and fluence high enough to reach the interior of the station and trigger our detector. For these events we plan to observe the temporal profile and the nuclear abundances.
- *Survey of different locations of the ISS modules.* By relocating and rotating the instrument it is possible to study the differences in flux and nature

of cosmic rays due to the different shielding of the station material (hull, racks, instruments etc.). Flux is also dependent on station attitude and orientation: currently several locations in the Pirs (Russian docking) and in the Service Modules (Central area, crew cabins) have been studied. In the future it is planned to make measurements in the Columbus module and in the US section of the station.

- *Study of the effectiveness of shielding materials.* Different materials are being considered to reduce the dose to the astronauts: the current approach in weight effective shielding in space is to use low Z materials for their higher stopping power and fragmentation cross-section of the projectile. In this way it is possible to reduce the LET (Linear Energy Transfer) and the quality factor of the radiation, thus reducing the equivalent dose to the astronauts. Although several steps are being taken in this direction (such as putting water reserves in the crew quarters) the best materials from this standpoint are often not practical. For instance, liquid hydrogen would be the best shielding material but cannot be used for the dangers involved in handling such a material. In the Altciriss project we are currently employing two set of tiles to study the effect of shielding on the nuclear radiation field:
 - (1) Polyethylene tiles. These are similar to what currently is used in the crew cabin of the US section of the ISS. These tiles are located on top and bottom of the bidirectional acceptance window of the detector to evaluate the effect of this material (for a thickness of $\simeq 5g/cm^2$) on the radiation and the nuclear abundances. Passive dosimeters are interposed between the detector and the shielding tile to compare the dose measured with TLD and CR-39 with active data coming from Sileye-3/Alteino.
 - (2) Multimaterial tiles. These tiles are divided into four sections, each composed of a different material: Polyethylene, Kevlar, Nextel/Capton Composite and one section left empty as a reference. These tiles were used in 2005 in the framework of the second Italian Soyuz Mission. In the Altciriss project they have until now been used with passive dosimeters interposed between the shielding tiles to measure the radiation dose.
- *Comparison with other detectors.* Given the complexity of the radiation field in space, in order to build a comprehensive picture of the cosmic ray environment on board the ISS it is necessary to correlate the measurements obtained with Sileye-3/Alteino with other detectors on board the station. To this purpose the device was located in the starboard cabin close to the Matroska-R spherical phantom. Furthermore a cross-comparison measurement campaign with the ESA Matroska(26) facility is planned to be carried forth during expedition 15: in this case Sileye-3 will be placed at the same locations as the human phantom (but not at the same time) to have the exact comparison of the cosmic ray flux. Comparison of the nuclear abundances measured with NASA IV-CPDS will also be performed. To study the propagation of cosmic rays in the Earths magnetosphere and from the exterior to the interior of the station the data coming from the Pamela experiment(27), a satellite borne cosmic ray detector placed in a 350*650

km, 70° inclination will be used.

3 Sileye-3/Alteino characteristics

Sileye-3 is a cosmic-ray detector composed of 8 silicon strip detector planes, each divided in 32 strips, with 2.5 mm pitch. There are 4 planes oriented along the X view and 4 planes along the Y view. The general scheme of the detector is shown in Figure 1; a detailed description of the apparatus and its functioning scheme can be found in (29; 30; 31). The device has a dynamic range capable of detecting particles from He to above Iron. Also non-relativistic protons releasing a signal above 1 mip¹ can trigger the apparatus. Geometrical factor is $23.78 \text{ cm}^2 \text{ sr}$, considering that particles from both sides can trigger the detector. Data are then stored in a temporary buffer to be sent via an ISA interface to a storage and data handling computer, a PC-104 board based on an AMD586 100 Mhz. A quartz clock is used to save event time; the beginning of each session is written to synchronize (in the off-line stage) the station time with the event time. Data are stored on standard PCMCIA cards. Their contents can be downloaded to the ground via telemetry, although usually only data samples relating to one day of acquisition are transferred using this procedure. The used cards are sent to the ground with the Soyuz and the ISS crew at the end of each increment. New cards are uploaded with Soyuz or Progress.

4 Passive Dosimeters

A number of passive dosimeters is used to measure the dose absorbed in space in the shielded and unshielded configuration and complement the active data coming from Sileye-3. These dosimeters come from JAXA, DLR and Napoli Federico II University and consist of different types of TLD and CR39 detectors. They are placed in four pouches:

- two pouches with all dosimeters are interposed between the two polyethylene shielding tiles and the acceptance windows of Sileye-3 when performing measurements in the shielded configuration (and thus are shielded by roughly 2π polyethylene). When the Silicon detector is performing unshielded measurements the tiles and pouches are packed close one to the other and placed near the device (and the dosimeters are behind 4π polyethylene shielding).

¹ Minimum Ionizing Particle. It is defined as the average energy lost in the detector by a minimum ionizing ($\simeq 2 \text{ GeV}$ proton)

- one pouch with four Federico II dosimeters is placed behind the multimaterial tile. Four samples of TLDs and CR39 are present in the unpackaged configuration and are located behind each material to facilitate the alignment between different materials and maximize the shielding geometrical factor.
- a control pouch with all dosimeters. This pouch is kept with data cards close to the detectors and moves to the different locations of the station.
- a ground control pouch follows the others in all phases up to launch in Baikonur.

The pouches are rotated every 6 months, with each taxi flight; except for the first set of material that was launched at the end of December and returned in April the duration was shorter.

5 Survey of the radiation environment in the ISS

Data cards, dosimeters and polyethylene shielding necessary for the experiment were first sent on board ISS on 21-12-05 with a Progress craft. The detector was switched on 24-12-05 in the Pirs module in the unshielded configuration. A first data sample of 40 hours was downlinked to the ground to verify the correct functioning of the device. Subsequently two long term sessions with and without shielding material (respectively 11 and 15 days) in the Pirs module were performed. In January 2006 the measurement campaign in the Russian Service module started: up to now the device has been located in both cabins and in several locations of the main area. In Figure 2 is shown the setup of the experiment in the Pirs/Docking module where the detector was first located. It is possible to see the active detector and the shielding material pouches containing the dosimeter bags. For each position it has been tried (keeping into account all constraints of logistics and observational time) to have a shielded and an unshielded measurement; acquisitions with different orientations at the same location have also been performed to assess the differences in flux and nuclear abundances due to different shielding material.

6 Flight data and nuclear identification capabilities

In Figure 3 is shown the acquisition event rate as a function of time for a sample of the dataset. Flux modulation is due to the geomagnetic shielding, with higher rate at the poles, where the cutoff is lower and lower rate at the equator where the shielding is higher. The highest peaks occur during passage in the South Atlantic Anomaly (SAA), where particle rate increases more than one order of magnitude due to the trapped proton component.

Correlating particle flux with position information it is possible to build an all particle map (see Figure 4) which shows the latitude increase at high latitude due to galactic particles and the SAA peak due to trapped protons.

A typical cosmic-ray event, in this case a neon nucleus crossing the device, is shown in Figure 5 (Top). One of the characteristics of Sileye-3 is its independent channel readout which allows acquisition of multi-particle events due to showers initiated with the interaction of primary particles with the hull or the equipment of the ISS: Figure 5 (Bottom) shows a typical event with this topology. To identify nuclei it is necessary to select single tracks crossing the eight planes of the detector (noise is removed from the events). The energy lost E_{loss} in silicon has been normalized to vertical incidence $E_{loss\,norm.}$ according to the formula: $E_{loss\,norm.} = E_{loss}\cos(\theta_{inc})$, with θ_{inc} the angle of incidence from the normal of the silicon planes. An additional cut, requiring that the energy released in the first and the last planes does not differ by more than 20%, selects particles of energy $E_{kin} \gtrsim 70\text{ MeV}/n$ (for Carbon, increasing with Z up to 150 MeV/n for Fe) . Since the average energy loss of nuclei in matter is described by the Bethe Block formula it basically depends from Z^2/β^2 , with $\beta = v/c$ and v the velocity of the impinging particle. Given the differential energy spectrum of cosmic rays hitting the detector, the value of β (and thus the energy lost in the detector) of most particles selected with the above mentioned cut is close to 1, with a smaller² amount of low energy particles with a lower β , resulting in a higher energy release tail enlarging the sigma of the gaussian peak. The peak is further spread according to the Landau distribution, which describes the distribution of energy loss in matter. Using the calibration obtained in (31) particle charge Z is obtained according to the following formula:

$$Z = \sqrt{\frac{E_{loss}(ADC) + 3211.2}{371.04}} \quad (1)$$

It is therefore possible to derive the spectrum for nuclei up to and above Iron, shown in Figure 6, in this case referring to 11 days of data taking in the unshielded configuration in the Pirs Module. It is possible to distinguish the peaks from C to Fe (sigma of gaussian fit for C is 0.3 charge units), with the even Z nuclei more abundant and evident than the odd, as found in cosmic rays. Nuclear abundances and trigger efficiency in the different configurations is currently being evaluated. The active nature of the device allows for charge determination to be performed in different points of the orbit and different geomagnetic cutoff regions. Also abundance comparison spectra with/without shielding will contribute to the determination of effectiveness of shielding materials in space.

² For instance, 84% of Carbon nuclei in cosmic rays have $1/\beta^2 < 1.2$.

7 Conclusions

In this work we have outlined the primary goals and presented preliminary results of the Altrcriss project on board the International Space Station. The data gathered up to now are under analysis and will be useful for determining of the radiation environment on board the station and the validation of Montecarlo transport codes. These measurements will be compared with those obtained with a large area detector, the Altea facility(32), sent to the ISS on July 2006. Altea will also continue to investigate the LF phenomenon and the cosmic ray radiation in space.

8 Acknowledgements

We wish to thank all ESA and Energia staff, in particular M. Heppener, E. Istasse, C. Mirra, A. Petrivelli, I. Nikolaiev, A. Savchenko and H. Stenuit for their invaluable support and help in planning and execution of the experiment.
